

**EFFECTS OF MANAGEMENT PRACTICES  
ON WETLAND BIRDS:  
MARSH WREN**

Grasslands Ecosystem Initiative  
Northern Prairie Wildlife Research Center  
U.S. Geological Survey  
Jamestown, North Dakota 58401

This report is one in a series of literature syntheses on North American wetland birds. The need for these reports was identified by the Prairie Pothole Joint Venture (PPJV), a part of the North American Waterfowl Management Plan. The PPJV adopted a goal to stabilize or increase populations of declining grassland- and wetland-associated wildlife species in the Prairie Pothole Region. To further that objective, it is essential to understand the habitat needs of birds other than waterfowl, and how management practices affect their habitats. The focus of these reports is on management of breeding habitat, particularly in the northern Great Plains.

Species for which syntheses are available or are in preparation:

Eared Grebe	Marbled Godwit
American Bittern	Wilson's Phalarope
Virginia Rail	Black Tern
Sora	Marsh Wren
Yellow Rail	Sedge Wren
American Avocet	Le Conte's Sparrow
Willet	Nelson's Sharp-tailed Sparrow
Long-billed Curlew

## ORGANIZATION AND FEATURES OF THIS SPECIES ACCOUNT

Information on the habitat requirements and effects of habitat management on wetland birds were summarized from information in more than 500 published and unpublished papers. A *range map* is provided to indicate the relative densities of the species in North America, based on Breeding Bird Survey (BBS) data. Although the BBS may not capture the presence of elusive waterbird species, the BBS is a standardized survey and the range maps, in many cases, represent the most consistent information available on species' distributions. Although birds frequently are observed outside the breeding range indicated, the maps are intended to show areas where managers might concentrate their attention. It may be ineffectual to manage habitat at a site for a species that rarely occurs in an area. The species account begins with a brief *capsule statement*, which provides the fundamental components or keys to management for the species. A section on *breeding range* outlines the current breeding distribution of the species in North America, including areas that could not be mapped using BBS data. The *suitable habitat* section describes the breeding habitat and occasionally microhabitat characteristics of the species, especially those habitats that occur in the Great Plains. Details on habitat and microhabitat requirements often provide clues to how a species will respond to a particular management practice. A *table* near the end of the account complements the section on suitable habitat, and lists the specific habitat characteristics for the species by individual studies. The *area requirements* section provides details on territory and home range sizes, minimum area requirements, and the effects of patch size, edges, and other landscape and habitat features on abundance and productivity. It may be futile to manage a small block of suitable habitat for a species that has minimum area requirements that are larger than the area being managed. The section on *brood parasitism* summarizes information on intra- and interspecific parasitism, host responses to parasitism, and factors that influence parasitism, such as nest concealment and host density. The impact of management depends, in part, upon a species' nesting phenology and biology. The section on *breeding-season phenology and site fidelity* includes details on spring arrival and fall departure for migratory populations in the Great Plains, peak breeding periods, the tendency to reneest after nest failure or success, and the propensity to return to a previous breeding site. The duration and timing of breeding varies among regions and years. *Species' response to management* summarizes the current knowledge and major findings in the literature on the effects of different management practices on the species. The section on *management recommendations* complements the previous section and summarizes recommendations for habitat management provided in the literature. The *literature cited* contains references to published and unpublished literature on the management effects and habitat requirements of the species. This section is not meant to be a complete bibliography; a searchable, annotated bibliography of published and unpublished papers dealing with habitat needs of wetland birds and their responses to habitat management is posted at the Web site mentioned below.

**Marsh Wren**  
(*Cistothorus palustris*)

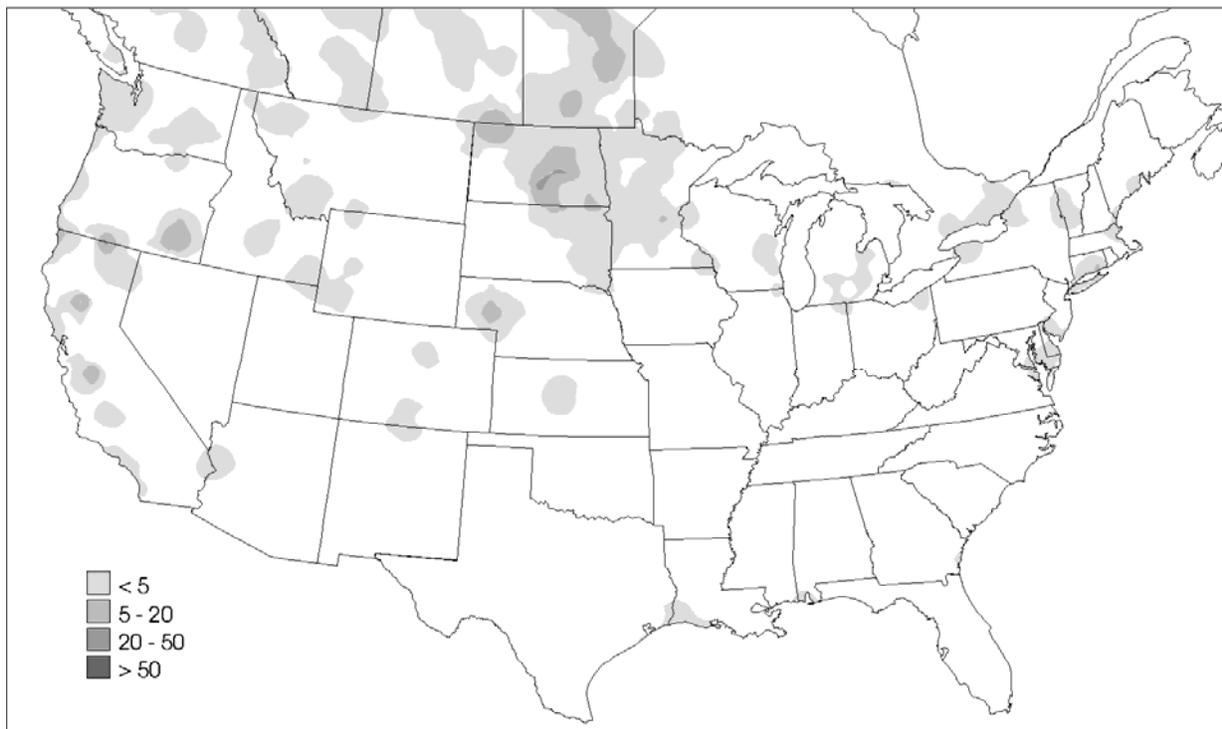

Figure. Breeding distribution of the Marsh Wren in the United States and southern Canada, based on Breeding Bird Survey data, 1985-1991. Scale represents average number of individuals detected per route per year. Map from Price, J., S. Droege, and A. Price. 1995. *The summer atlas of North American birds*. Academic Press, London, England. 364 pages.

Key to management is maintaining wetlands that have dense stands of emergent vegetation.

Breeding Range:

Marsh Wrens breed from western British Columbia east through southern Manitoba, Ontario, Quebec, Newfoundland, and New England, south to California, western Arizona, northern New Mexico, central Kansas, and the Gulf Coast, and east through central Missouri, Illinois, Indiana, Ohio, Pennsylvania, and the Atlantic Coast (National Geographic Society 1999). (See figure for the relative densities of Marsh Wrens in the United States and southern Canada, based on Breeding Bird Survey data.)

Suitable habitat:

Marsh Wrens occupy fresh to brackish fen, seasonal, semipermanent, or permanent wetlands with dense, mixed, or monotypic stands of emergent aquatic vegetation such as cattail (*Typha* spp.), hardstem bulrush (*Schoenoplectus acutus*), river bulrush (*Schoenoplectus fluviatilis*), alkali bulrush (*Scirpus maritimus*), hairy sedge (*Carex lacustris*), bur-reed (*Sparganium eurycarpum*), and common reed (*Phragmites australis*) (Stewart and Kantrud 1965;

Willson 1967; Burt 1970; Krapu and Duebbert 1974; Stewart 1975; Faanes 1981,1982; Kantrud and Stewart 1984; Burger 1985; Leonard 1986; Gutzwiller and Anderson 1987; Leonard and Picman 1987*a,b*; Peck and James 1987; Picman et al. 1993; Faanes and Lingle 1995; Prescott et al. 1995; Kroodsma 1997; Naugle 1997). Marsh Wrens are less commonly found in stands of bluejoint (*Calamagrostis canadensis*) and reed canary grass (*Phalaris arundinacea*) because these plant types are shorter and have less stem strength than more robust emergents such as cattail (Gutzwiller and Anderson 1987). Marsh Wrens may be found along the banks of slow-moving rivers where emergent vegetation has developed (Johnsgard 1980). In North Dakota, highest densities of Marsh Wrens were found in fen wetlands, followed by semipermanent and seasonal wetlands (Kantrud and Stewart 1984). In Minnesota, Marsh Wrens were found in woody vegetation <1.5 m tall or in tame grasses adjacent to wetlands (Niesar 1994). Marsh Wrens also have been observed in restored wetlands (Delphey 1991, Hemesath 1991, Svedarsky 1992, Delphey and Dinsmore 1993, Hemesath and Dinsmore 1993, VanRees-Siewert 1993, Hartman 1994, Schreiber 1994, VanRees-Siewert and Dinsmore 1996, Kroodsma 1997, Schuster 1998).

In seasonal wetlands in eastern South Dakota, the presence of Marsh Wrens was significantly and positively related to the percent of wetland area that was vegetated, dominance of thick-stemmed emergent plants, and presence of untilled land surrounding the wetland (Naugle 1997). In semipermanent wetlands, the presence of Marsh Wrens was positively related to the percent of wetland area that was vegetated and to dominance of thick-stemmed plants. Preliminary data from D. H. Johnson (*unpublished data*) indicated that in North Dakota and South Dakota, number of breeding pairs of Marsh Wrens was highest in temporary, seasonal, and semipermanent wetlands and was lowest in alkali and permanent wetlands. Number of pairs was higher in restored wetlands than in natural wetlands, and on public land than on private land. Number of breeding pairs increased with increasing amounts of emergent vegetation to a point at which breeding pairs leveled off. Marsh Wrens were more common in wetlands that had semipermanent wetlands within 0.4 km than in wetlands without semipermanent wetlands nearby.

In Iowa, Marsh Wrens were more likely to be present in natural wetlands than in restored wetlands (Fairbairn and Dinsmore 2001*a*). The occurrence of Marsh Wrens was positively related to habitat diversity, which was a measure of the evenness of distribution of vegetation zones within a wetland. Density was positively related to the percent of wetland area within a wetland complex that was composed of wet-meadow vegetation, and to the area of emergent vegetation within a complex (Fairbairn and Dinsmore 2001*b*). Complexes were defined as tracts of land containing from 4 to 15 wetlands ranging from 44 to 144 ha. Occurrence was negatively related to the percent area of a wetland composed of mud flat and percent area composed of open water (Fairbairn and Dinsmore 2001*a*). Density was negatively related to the ratio of total wetland perimeter to total area of wetlands within a complex (Fairbairn and Dinsmore 2001*b*). In Wisconsin, density of Marsh Wrens varied according to habitat type (Manci and Rusch (1988). Densities were higher in stands of shallow- and deep-water cattails than in stands of river bulrush and dry cattails. Water depth in shallow-water cattail stands averaged 5 cm in early June, deep-water cattail stands averaged 29 cm in early June, dry cattail stands contained no standing water by late June, and river bulrush contained standing water until mid-August. In Alberta, Marsh Wrens were present in wetlands surrounded by newly planted dense nesting

cover, but were absent from wetlands surrounded by cropland (Prescott et al. 1993). In Manitoba, densities and nest success were higher in a more heterogeneous wetland that supported mixed stands of cattail, common reed, and hardstem bulrush than in a wetland that supported homogeneous stands of cattail (Leonard 1986, Leonard and Picman 1987b). The heterogeneous wetland had taller (29 cm versus 12 cm), denser (measurements not given) vegetation and deeper (132 cm versus 92 cm) water than the homogeneous wetland.

Marsh Wrens nest over water or damp ground in domed structures anchored to emergent vegetation (Burt 1970, Salt and Salt 1976, Burger 1985, Picman 1986, Peck and James 1987, Kroodsma 1997). In Iowa, 96% of 227 nests were located in hairy sedge (Burt 1970). Nest locations indicated that Marsh Wrens were not selecting nest sites based on distance to open water or distance to a different vegetative cover type (vegetative cover types included cattail, hairy sedge, bluejoint, bur-reed, sweetflag [*Acorus americanus*], river bulrush, or prairie cordgrass [*Spartina pectinata*]). The height above water of 93 nests averaged 32 cm and ranged from 28 to 112 cm. In North Dakota, 88% of 25 nests were located in cattail, alkali bulrush, or mixtures of hardstem bulrush and sprangletop (*Scolochloa festucacea*) (Stewart 1975). Additional nests were located in river bulrush, hardstem bulrush/alkali bulrush, and cattail/sprangletop. The height of 23 nests above water averaged 41 cm and ranged from 18 to 63.5 cm. The water depth at 19 nests in North Dakota averaged 30 cm and ranged from 0 to 48 cm (Stewart 1975). In another North Dakota study, the height above water of eight nests averaged 12 cm (Krapu and Duebbert 1974). In Minnesota, Marsh Wren nests were found in stands of reed canary grass and timothy (*Phleum pratense*) (Svedarsky 1992). Nests in a restored wetland in Minnesota were found in stands of cattail, bulrush, and common reed (Svedarsky 1992). In Ontario, Marsh Wrens most commonly nested in stands of cattail; elevated nests were most often found in cattail (38% of 476 nest records) and less often in bulrush, grass, sedge, horsetail (*Equisetum* sp.), bur-reed, loosestrife (*Lythrum*), spiraea (*Spiraea*) or willow (*Salix*) (Peck and James 1987). The height of 234 nests ranged from 0.2 to 1.5 m above water. The vegetation supporting nests was usually dead, sometimes living, or a combination of both. Locations of 14 nests ranged from being adjacent to open water to 91 m from it, and water depths at 31 nests ranged from 5 to 91 cm. In Washington, Marsh Wrens preferred building nests in broad-leaved cattail (*Typha latifolia*) as long as standing water was present (Verner and Engelsen 1970). As cattail stands dried out, birds abandoned cattail stands to nest in stands of softstem bulrush (*Schoenoplectus tabernaemontani*) located in standing water. Presence of water could serve as protection against predation or to increase available food sources. Nest height of 81 nests used for breeding (as opposed to unoccupied nests) ranged from 76 to 93 cm (Verner 1965). Nest height of 548 unoccupied nests ranged from 80 to 95 cm.

In Manitoba, successful nests were surrounded by a significantly greater number of inactive multiple nests than were depredated nests. In Washington, pairing success (defined as the number of mates a male acquired) was positively correlated with total nest sites in a territory (Verner and Engelsen 1970). Male Marsh Wrens build multiple nests within individual territories, but only one is chosen by the female as a nest site; less commonly, new nests are built by females (Provost 1947, Burt 1970, Leonard 1986, Leonard and Picman 1987a, Metz 1991, Kroodsma 1997). Verner (1965) found that males build from 11 to 32 nests. Multiple nests may serve to increase nest success by decreasing the probability that a searching predator will find an active nest (Verner and Engelsen 1970, Leonard and Picman 1987a). Multiple nests also may

indicate to females the presence of an ample food supply in that males have more time to build multiple nests because of less time needed to forage (Verner and Engelsen 1970). A table near the end of the account lists the specific habitat characteristics for Marsh Wrens by study.

#### Area requirements:

One study in Manitoba calculated mean territory sizes for two sites (Leonard and Picman 1986). One site was 6 ha and was dominated by a homogeneous stand of cattail. The mean territory size of 13 males was 0.08 ha. The second site was 4 ha and was a more heterogeneous wetland containing stands of common reed, cattail, and hardstem bulrush. The mean territory size of 16 males was 0.11 ha. In Minnesota, Burns (1982) suggested that Marsh Wren territories were about 0.03 ha. In Washington, territory size varied from 0.005 to 0.34 ha (Verner 1965, Verner and Engelsen 1970). The territory size of Marsh Wrens may be affected by interspecific competition with Yellow-headed Blackbirds (*Xanthocephalus xanthocephalus*); Leonard and Picman (1986) found that Marsh Wren territories significantly increased in size following the departure of Yellow-headed Blackbirds from early to mid-July. Territories expanded into portions of the wetland with deeper water, which were areas formerly occupied by Yellow-headed Blackbirds. In Iowa, Marsh Wrens were present in all wetland size categories (<5 ha, 5-20 ha, and >20 ha) (Brown and Dinsmore 1986). In Manitoba, Marsh Wrens were present in wetlands of all size categories studied, ranging from <1 to 19.3 ha (Daub 1993). In Alberta, Marsh Wrens were present in wetlands ranging from 1 to >8 ha (upper size limit not given) (Prescott et al. 1995).

#### Brood parasitism:

Brood parasitism by Brown-headed Cowbirds (*Molothrus ater*) is rare due to the Marsh Wren's characteristic dome-shaped nest and small entrance hole (Picman 1986, Kroodsma 1997). In British Columbia, Picman (1986) found that only one of 1200 nests was parasitized. The nest contained one cold, undamaged cowbird egg and two broken Marsh Wren eggs.

#### Breeding-season phenology and site fidelity:

Marsh Wrens arrive on their breeding grounds from April to early May and depart from mid-August through October (Provost 1947, Bent 1964, Stewart 1975, Salt and Salt 1976, Knapton 1979, Johnsgard 1980, Faanes 1981, Leonard 1986, Janssen 1987, Leonard and Picman 1987b, Kent and Dinsmore 1996, Kroodsma 1997). The peak breeding season in North Dakota occurs from late May to early August (Stewart 1975). Arrival of females occurs 7-10 d following the arrival of males (Leonard 1986, Leonard and Picman 1987b, Kroodsma 1997). Renesting after the failure of an initial clutch and double-broodedness are common (Verner 1965, Peck and James 1987, Kroodsma 1997). Marsh Wrens use one of their multiple nests for renesting after the destruction of the initial nest. Breeding-site fidelity is low (Leonard 1986, Leonard and Picman 1987b). In Manitoba, 10% of 41 marked males returned to the same wetland in the second year of the study and 7% of 28 males returned in the third year (Leonard and Picman 1987b). Only one of 540 marked young returned to the banding area. In Washington, 17% of 76 adult males returned to the study site the following year (Verner 1971). Of these 13 returning males, mean distance between breeding territories from one year to the next year was 386 m, and five males held the same territory as the previous year. Based on 10

first-year males, average distance between rearing territories and first breeding territories was 1951 m. Only one of the 10 males had its breeding territory on the same lake where it was reared.

#### Species' response to management:

Little is known concerning the effects of burning, mowing, or grazing on Marsh Wrens. In South Dakota, the presence of Marsh Wrens was negatively related to the intensity of livestock grazing along shorelines of seasonal wetlands (Naugle 1997). In Nebraska, Marsh Wrens were negatively affected by the loss of wetlands by drainage to accommodate expanded agricultural production (Faanes and Lingle 1995). In Iowa, water levels of a 160-ha semipermanent wetland were experimentally manipulated to observe the effects on wetland-nesting species (Weller and Fredrickson 1973). The wetland was reflooded 1 yr after drawdown, after vegetation had germinated and become established. Marsh Wrens were present the year of reflooding and for the next 4 yr. Populations declined 5 and 6 yr after reflooding as the amount of emergent vegetation declined due to inundation by deep water.

Wetlands that have been modified for waterfowl production are commonly used by Marsh Wrens (Brady 1983). In eastern South Dakota, Marsh Wrens were found in dug-brood complexes (system of channels, ponds, and human-created islands constructed on wetlands to provide deep, open water and upland nesting areas for waterfowl) (Brady 1983). Marsh Wrens nested in stands of cattail and bulrush along the shorelines of islands in the dug-brood complexes. Although they were common in both habitats, Marsh Wren densities were higher in unmodified wetlands than in the dug-brood complexes.

Marsh Wrens readily colonize restored wetlands (Hemesath 1991, Svedarsky 1992, Hemesath and Dinsmore 1993, Hartman 1994, Kroodsmas 1997). In Iowa, Marsh Wrens have been found to nest in restored wetlands, although densities were higher in natural wetlands (Delphey 1991, Delphey and Dinsmore 1993, Schreiber 1994, Schuster 1998). In other Iowa studies, Marsh Wrens nested in restored wetlands 1-5 yr following restoration; studies did not examine restored wetlands older than 5 yr (Hemesath and Dinsmore 1993, VanRees-Siewert 1993, Schreiber 1994, VanRees-Siewert and Dinsmore 1996). In Indiana, Marsh Wrens occurred in restored wetlands, but not natural wetlands, although the number of natural wetlands sampled was small (Hartman 1994). Restored wetlands often lack wet-meadow zones (VanRees-Siewert 1993, VanRees-Siewert and Dinsmore 1996, Schuster 1998). In Iowa, the absence of wet-meadow zones in restored wetlands may have restricted the use of these wetlands by Marsh Wrens (VanRees-Siewert 1993, VanRees-Siewert and Dinsmore 1996). Hemesath and Dinsmore (1993) found that emergent cover was greater in restored wetlands drained  $\leq 30$  yr ago than restored wetlands drained  $>30$  yr ago. Emergent cover is an important habitat requirement for Marsh Wrens and the age of a drained wetland may need to be considered when selecting suitable sites for restoration.

Conversion of wetlands to cranberry (*Vaccinium macrocarpon*) beds may negatively affect Marsh Wrens because commercial cranberry production requires scraping away native vegetation and soils, ditching, diking, and depositing sand (to provide drainage for the cranberry beds) (Jorgensen and Nauman 1993). Extensive road systems also are built to provide access for maintaining the cranberry beds. In Wisconsin, Marsh Wrens occupied natural habitat within 100 m of the cranberry beds, but they avoided the cranberry beds themselves. Edges created

between the cranberry beds and the surrounding native vegetation resulted in higher numbers of Brown-headed Cowbirds in the cranberry beds than in areas near water impoundments.

In North Dakota, glyphosate (N-[phosphonomethyl] glycine) herbicide was aerially applied at a rate of 5.8 L/ha to reduce cattail in 23 wetlands (Linz et al. 1996). Wetland area was treated at 50%, 70%, or 90% spray coverage. Marsh Wren densities were monitored once immediately prior to treatment and for 2 yr following treatment. Based on seven control wetlands and 16 treated wetlands, densities were significantly higher in control wetlands than in wetlands in all treatment levels combined (2.21 birds/ha versus 0.66 birds/ha, respectively). Based on two wetlands within each treatment, densities were greater in wetlands with 50% spray coverage than wetlands with 90% spray coverage (1.04 birds/ha versus 0.26 birds/ha, respectively). Following treatment, densities of Marsh Wrens were positively related to percent cover of live vegetation, negatively related to percent cover of dead vegetation, and not affected by percent open water. In Wisconsin, open water areas were created by eliminating cattails using Amitrol\* (1H-1,2,4-triazole-3-ylamine), Radapon or Dowpon (both 2,2-dichloropropionic acid) (Beule 1979). Amitrol and Radapon were applied at rates ranging from 3.85 to 34 kg/ha. Application rates for Dowpon ranged from 5.6 to 10 kg/ha. Marsh Wrens preferred to nest in living, green cattail stands rather than in dead, residual cattail stands.

Marsh Wren mortalities due to collisions with television towers have been reported in Iowa and North Dakota (Avery and Clement 1972, Dinsmore et al. 1987). Casualties occurred during nights with overcast skies. Both adults and juveniles were susceptible (Dinsmore et al. 1987).

### **Management Recommendations:**

With the exception of VanRees-Siewert (1993) and VanRees-Siewert and Dinsmore (1996), no species-specific management recommendations were found for Marsh Wrens. The management recommendations that follow are based on habitat requirements or apply to the community of wetland bird species as a whole.

Marsh Wrens require dense, robust, vegetatively heterogeneous stands of emergent vegetation (Leonard 1986, Kroodsma 1997). The long-term protection of wetlands can be achieved through conservation easements and purchases of wetland basins (VanRees-Siewert 1993, VanRees-Siewert and Dinsmore 1996). Protecting wetlands >10 ha in size will maintain area-dependent species, decrease the proportion of habitat edge, and decrease brood parasitism by Brown-headed Cowbirds (Daub 1993). Protection and restoration of a diversity of wetland types and sizes, and wetlands with a diversity of vegetation zones, is of primary management importance to provide habitat regardless of water conditions in a given year (Fairbairn and Dinsmore 2001*b*). When selecting wetlands for protection or restoration, the number of other

---

\*References to chemical trade names does not imply endorsement of commercial products by the Federal Government.

wetlands in the surrounding landscape and the number of wetlands that support emergent vegetation should be considered as a way to increase density of Marsh Wrens and increase species richness of other waterbird species.

Restoration projects should focus on creating a complex of various-aged wetlands to provide a variety of vegetational stages (Hemesath 1991, Schuster 1998). Restoration of recently (<30 yr ago) drained wetlands may promote quick regeneration of wetland vegetation (Hemesath 1991, Hemesath and Dinsmore 1993). In Iowa, emergent cover was greater in restored wetlands that were drained  $\leq 30$  yr ago than in wetlands drained  $>30$  yr ago. Restore wetlands that have not been effectively drained, such as those typically used for pasture or hayfields where there is less incentive to completely drain the area. Given that restored wetlands often lack a wet-meadow zone, wet-meadow species may need to be planted in long-since drained wetlands (VanRees-Siewert 1993, VanRees-Siewert and Dinsmore 1996). The absence of wet-meadow zones in restored wetlands may reduce the use of these wetlands by Marsh Wrens.

Grazing of wetlands may be detrimental if the vegetated wetland perimeter that protects nesting habitat and deters nest predators is eliminated (Naugle 1997). In South Dakota, presence of Marsh Wrens increased with percent of wetland area that was vegetated and with amount of untilled land adjacent to wetlands (Naugle 1997). In Alberta, Marsh Wrens appeared to prefer wetlands surrounded by dense nesting cover over wetlands surrounded by cropland (Prescott et al. 1993).

Marsh Wrens have been reported in wetlands of water depths varying from 0 to 132 cm (Stewart 1975, Leonard and Picman 1987*b*). Little is known about the effect of fluctuating water levels on Marsh Wrens. Experimental manipulation of a semipermanent wetland involving drawdown and reflooding resulted in Marsh Wrens inhabiting the wetland 1-4 yr after reflooding, and numbers of Marsh Wrens decreasing 5-6 yr after reflooding as water began to inundate vegetation (Weller and Fredrickson 1973). Reduction of cattail coverage may reduce populations of breeding Marsh Wrens (Linz et al. 1996). If cattail control must be conducted, treatments should be staggered in order to maintain various stages of cattail regeneration and growth (Linz et al. 1996). Beule (1979) provided general management recommendations for manipulating cattail growth.

Table. Marsh Wren habitat characteristics.

Author(s)	Location(s)	Habitat(s) Studied*	Species-specific Habitat Characteristics
Beule 1979	Wisconsin	Wetland	Preferred nesting in living cattail ( <i>Typha</i> spp.) stands rather than in dead, residual cattail stands
Brady 1983	South Dakota	Wetland, wetland (modified)	Nested in stands of cattail and bulrush ( <i>Scirpus</i> spp.) along the shorelines of islands and channels in dug-brood complexes (modified wetlands comprising a system of channels, ponds, and human-created islands to provide deep, open water and upland nesting areas for waterfowl) and in unmodified semipermanent wetlands; densities were higher on unmodified wetlands
Brown and Dinsmore 1986	Iowa	Wetland	Occurred in semipermanent and seasonal wetlands consisting of 40-60% open water and ranging in size from <1 ha to >20 ha
Burger 1985	Rangewide	Wetland	Built cup-shaped nests attached to cattail stems
Burt 1970	Iowa	Wetland	Majority (218 of 227) of nests were located in hairy sedge ( <i>Carex lacustris</i> ), four nests were in sweetflag ( <i>Acorus americanus</i> ), two in tussock sedge ( <i>Carex tuckermanni</i> ), two in river bulrush ( <i>Schoenoplectus fluviatilis</i> ), and one in bur-reed ( <i>Sparganium eurycarpum</i> ); height above water of 93 nests averaged 32 cm and ranged from 18 to 112 cm; 35% of 179 nests were located within 6 m of open water; only 36% of 247 nests were located within 6 m of an edge between two different vegetative cover types

Daub 1993	Manitoba	Wetland	Occurred in wetlands ranging in size from 0.1 to 19.3 ha
Delphey 1991, Delphey and Dinsmore 1993	Iowa	Wetland, wetland (restored)	Densities were higher in natural wetlands than in restored wetlands, although nesting occurred in both natural and restored wetlands
Faanes 1982	North Dakota	Cropland, mixed-grass, wetland, woodland	Occurred in dense growths of cattail and hardstem bulrush ( <i>Schoenoplectus acutus</i> ) on the periphery of semipermanent and permanent wetlands
Faanes and Lingle 1995	Nebraska	River channel island, wetland	Nesting densities were highest in prairie wetlands, followed by river channel islands
Fairbairn and Dinsmore 2001a,b	Iowa	Wetland complex	More likely to be present in natural wetlands than in restored wetlands; occurrence was positively related to habitat diversity, which was a measure of the evenness of distribution of vegetation zones within a wetland, and negatively related to the percent area of a wetland composed of mud flat and percent area composed of open water; density was positively related to the percent of wetland area within a wetland complex that was composed of wet-meadow vegetation and to the area of emergent vegetation within a complex, and negatively related to the ratio of total wetland perimeter to total area of wetlands within a complex; complexes were defined as tracts of land containing from 4 to 15 wetlands ranging from 44 to 144 ha
Hartman 1994	Indiana	Wetland, wetland (restored)	Occurred in restored wetlands but not in natural wetlands

Hemesath 1991, Hemesath and Dinsmore 1993	Iowa	Wetland (restored)	Nested in 1- to 3-yr old restored wetlands
Johnsgard 1980	Nebraska	Wetland	Occurred in freshwater wetlands with extensive emergent vegetation and along banks of slow-moving rivers with developing emergent vegetation
Kantrud and Stewart 1984	North Dakota	Wetland	Densities were highest in fens, followed by semipermanent and seasonal wetlands
Krapu and Duebbert 1974	North Dakota	Wetland	Nested in dense cattail stands; mean water depth at eight nests was 29 cm; height above water of eight nests averaged 12 cm
Leonard 1986	Manitoba	Wetland	Water depth and maximum vegetation height at 26 nests in a vegetatively homogeneous wetland averaged 20.5 cm and 134.5 cm, respectively; water depth and maximum vegetation height at 33 nests in a vegetatively heterogeneous wetland averaged 20.6 cm and 162 cm, respectively
Leonard and Picman 1987 <i>b</i>	Manitoba	Wetland	Density and nest success were higher in a more heterogeneous wetland that consisted of mixed stands of cattail, common reed ( <i>Phragmites australis</i> ), and hardstem bulrush than in a wetland consisting of a homogeneous stand of cattail; nest success was higher in the more heterogeneous wetland, probably because it had taller (29 cm versus 12 cm), denser vegetation and deeper (132 cm versus 92 cm) water than the homogeneous wetland
Linz et al. 1996	North Dakota	Wetland	Following glyphosate herbicide treatment to control cattail, densities of Marsh Wrens were positively

			related to percent cover of live vegetation and negatively related to percent cover of dead vegetation
Manci and Rusch 1988	Wisconsin	Wetland	Densities were highest in shallow- and deep-water cattail stands, followed by river bulrush and dry cattail stands; water depth in shallow-water cattail stands averaged 5 cm in early June (sample sizes not given), deep-water cattail stands averaged 29 cm in early June, dry cattail stands contained no standing water by late June, and river bulrush contained standing water until mid-August
Naugle 1997	South Dakota	Conservation Reserve Program (idle seeded-native, idle tame), cropland, idle mixed-grass, idle tallgrass, idle tame, mixed-grass pasture, tallgrass pasture, tame pasture, wetland	Presence in seasonal wetlands was significantly and positively related to the percent of wetland area that was vegetated, dominance of thick-stemmed emergent plants, and presence of untilled land adjacent to wetlands; presence was negatively related to the intensity of grazing along shorelines of seasonal wetlands; presence in semipermanent wetlands was positively related to the percent of the wetland that was vegetated and dominance of thick-stemmed plants
Niesar 1994	Minnesota	Waterfowl Production Area (idle mixed-grass, idle tame), wetland, woodland	Occurred in wetlands and in brush or tame grasses adjacent to wetlands
Peck and James 1987	Ontario	Wetland	Nested adjacent to or $\leq 91$ m from open water; elevated nests most often were found in cattail (179 records) and

			less often in bulrush, grass, sedge, horsetail ( <i>Equisetum</i> sp.), bur-reed, loosestrife ( <i>Lythrum</i> ), spiraea ( <i>Spiraea</i> ) or willow ( <i>Salix</i> ); vegetation supporting nests usually was dead, sometimes living, or a combination of both; water depths at 31 nests ranged from 5 to 91 cm; height of 234 nests above water ranged from 0.2 to 1.5 m
Picman et al. 1993	Ontario	Wetland	Nested in a wetland with dense, uniform stands of cattails and water depth ranging from 0 to 120 cm
Prescott et al. 1993	Alberta	Cropland, dense nesting cover (idle seeded-native), mixed-grass pasture, tame pasture, wetland, wetland (restored)	Occurred in wetlands surrounded by newly (<1 yr) planted dense nesting cover, but were absent from wetlands surrounded by cropland
Prescott et al. 1995	Alberta	Wetland	Occurred in large (>8 ha) and medium (1-8 ha) sized fresh wetlands; absent from saline wetlands
Salt and Salt 1976	Alberta	Wetland	Nested in cattail and rushes ( <i>Juncus</i> spp.); nests were 0.3 to 1.2 m above water
Schreiber 1994	Iowa	Wetland, wetland (restored)	Frequency of occurrence and nest density were greater in natural wetlands than restored wetlands; Marsh Wrens first appeared and nested on 2-yr-old restored wetlands, and also nested on 4- and 5-yr-old restored wetlands
Schuster 1998	Iowa	Wetland, wetland (restored)	Frequency of occurrence and nest density were greater in natural wetlands than restored wetlands in one year, but were similar in natural and restored wetlands the

			next year
Stewart 1975	North Dakota	Wetland, wetland (restored)	Nests were located in cattail, alkali bulrush ( <i>Scirpus maritimus</i> ), and stands of hardstem bulrush and sprangletop ( <i>Scolochloa festucacea</i> ); height of 23 nests above water averaged 41 cm and ranged from 18 to 63.5 cm; water depth at 19 nests averaged 30 cm and ranged from 0 to 48 cm
Stewart and Kantrud 1965	North Dakota	Wetland	Densities were highest in fresh to brackish semipermanent wetlands with closed stands of emergent cover
Svedarsky 1992	Minnesota	Wetland (restored)	Nested in a stand of reed canary grass ( <i>Phalaris arundinacea</i> ) and timothy ( <i>Phleum pratense</i> ); nests in the restored wetland in Minnesota were found in stands of cattail, bulrush, and common reed
VanRees-Siewert 1993, VanRees-Siewert and Dinsmore 1996	Iowa	Wetland	Nested in 3- and 4-yr-old restored wetlands
Verner 1965	Washington	Wetland	Nest height of 548 dummy nests ranged from 80 to 95 cm; nest height of 81 breeding nests ranged from 76 to 93; based on 26 males, a range of 11 to 32 nests were completed per male
Verner and Engelsen 1970	Washington	Wetland	Preferred to nest in broad-leaved cattail ( <i>Typha latifolia</i> ) as long as standing water was present, but as cattail stands dried out, birds abandoned cattail stands to nest in stands of softstem bulrush ( <i>Schoenoplectus tabernaemontani</i> ) located in standing water; pairing success was negatively correlated with percent bulrush

			in a territory and positively correlated with total nest sites in a territory; area of pure cattail, area of pure bulrush, area of mixed cattail and bulrush, total area, percent pure cattail, and percent mixed cattail and bulrush were not correlated with pairing success
--	--	--	--

\*In an effort to standardize terminology among studies, various descriptors were used to denote the management or type of habitat. “Idle” used as a modifier (e.g., idle tallgrass) denotes undisturbed or unmanaged (e.g., not burned, mowed, or grazed) areas. “Idle” by itself denotes unmanaged areas in which the plant species were not mentioned. Examples of “idle” habitats include weedy or fallow areas (e.g., oldfields), fencerows, grassed waterways, terraces, ditches, and road rights-of-way. “Tame” denotes introduced plant species (e.g., smooth brome [*Bromus inermis*]) that are not native to North American prairies. “Hayland” refers to any habitat that was mowed, regardless of whether the resulting cut vegetation was removed. “Burned” includes habitats that were burned intentionally or accidentally or those burned by natural forces (e.g., lightning). In situations where there are two or more descriptors (e.g., idle tame hayland), the first descriptor modifies the following descriptors. For example, idle tame hayland is habitat that is usually mowed annually but happened to be undisturbed during the year of the study.
